Abstract

Horizontal distributions of expected or mean surface and bottom temperatures on the Northeast Continental Shelf from Cape Hatteras to the Gulf of Maine are presented for the beginning and middle of each month. Data used to generate these distributions are from the period 1977-87. The distributions, therefore, represent an 11-year mean annual temperature cycle. Horizontal distributions of the interannual variability in temperature within the 11-year period are also presented.

Introduction

At mid-latitudes, continental shelf waters exhibit a large seasonal change in temperature, warming in the spring and summer and cooling in the fall and winter. This annual cycle of temperature exerts a strong influence on the distribution and migratory habits of many fish species. It also influences the time of spawning for some species and may affect feeding and growth rate directly.

This report presents horizontal distributions of the expected or mean surface and bottom temperature on the Northeast Continental Shelf of the United States from Cape Hatteras to the Gulf of Maine for the beginning and middle of each month. The data used to generate these distributions are from the period 1977-87 and were obtained as part of the Marine Resources Monitoring, Assessment, and Prediction (MARMAP) program. MARMAP is an interdisciplinary program to measure the distribution of plankton, nutrients, and physical water properties over the continental shelf from Cape Hatteras to the Gulf of Maine (Sherman 1980). Summaries of other parameters measured by MARMAP may be found in Morse *et al.* (1987) and Sibunka and Silverman (1984).

The extreme temperatures in the water column are found generally at the surface and the bottom. The distributions presented, therefore, indicate the range of temperatures that likely would be encountered in the water column. The only consistent exception is in the Gulf of Maine during the spring and summer. There the coldest temperatures occur in an intermediate layer (50-125 m depth) and represent a remnant of the previous winter's cooling (Hopkins and Garfield 1979).

The MARMAP sampling included observations of salinity. The interannual variability in salinity of the shelf waters was found, however, to be as large or larger than the seasonal changes of salinity. Therefore, no characteristic annual cycle of salinity could be determined comparable to the temperature cycle presented in this report.

The Data

The MARMAP program made observations three to six times per year at over 180 standard station locations (Figure 1). The standard stations are separated by about 30 km; not all stations were occupied on each cruise. During 1977-87, hydrographic measurements were made on 49 MARMAP survey cruises.

Water properties were measured generally using water bottles and reversing thermometers at up to 15 standard

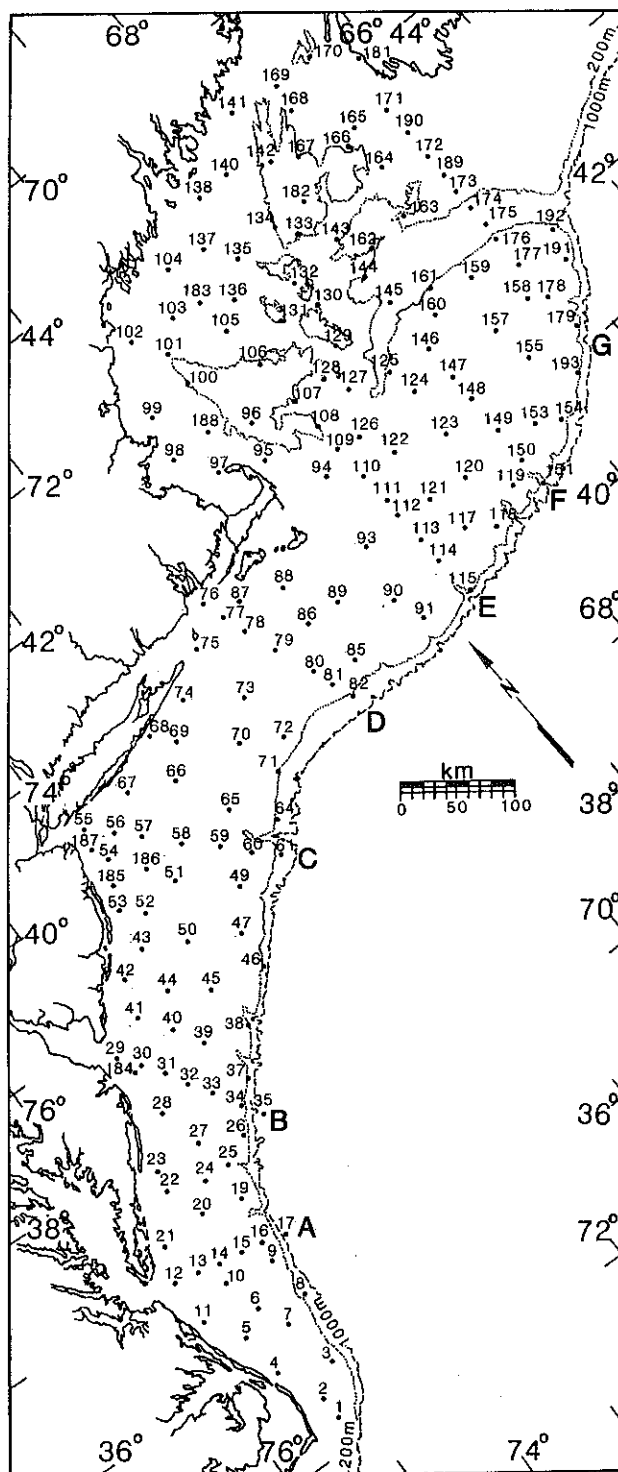

Figure 1. Location of MARMAP standard stations.

depths, although in 1987 a conductivity, temperature, and pressure profiling instrument (*i.e.*, CTD) was used on some cruises. The accuracy of the temperature data is approximately 0.02°C. For this report only, the surface and near-bottom temperature observations from the MARMAP data set were used. An observation had to be within 5 m of the surface to be considered a surface value and within 10 m of the bottom to be used as a bottom value.

Determining the Annual Temperature Cycle

The MARMAP data set supplies repeated observations of water properties at essentially fixed locations. The repeated sampling permits an analytical description of the annual cycle of surface and bottom temperature at a location. To do this, all of the observations at a MARMAP station were combined, regardless of year, with the dates expressed only as Julian day. If there were at least 10 observations for a station and at least one in each quarter of the year, an annual curve was calculated.

The annual curve fit to the data is the sum of three sinusoidal components which have frequencies of one, two, or three cycles per year. To fit the different harmonic components, a multiple regression model was used with the form:

$$T = \sum_{j=1,2,3} [M_j + A_j \cdot \cos(2\pi \cdot JD / P_j) + B_j \cdot \sin(2\pi \cdot JD / P_j)]$$

where:

- T = temperature;
- M_j = the mean temperature for the jth component;
- JD = Julian day;
- A_j = cosine amplitude for the jth component;
- B_j = sine amplitude for the jth component; and
- P_j = the harmonic period for the jth component.

The independent variables are the cosine and sine terms, evaluated for the Julian day of each observation and the harmonic period being considered. The model then has the form:

$$T = M + A \cdot X_1 + B \cdot X_2$$

where X₁ is the cosine variable and X₂ is the sine variable. The values of A and B were determined as follows (SPSS Inc. 1975):

$$A = \frac{SP[T,1] \cdot SS[2] - SP[T,2] \cdot SP[1,2]}{SS[1] \cdot SS[2] - SP[1,2] \cdot SP[1,2]}$$

$$B = \frac{SP[T,2] \cdot SS[1] - SP[T,1] \cdot SP[1,2]}{SS[1] \cdot SS[2] - SP[1,2] \cdot SP[1,2]}$$

$$M = T - A \cdot \bar{X}_1 - B \cdot \bar{X}_2$$

where SS stand for sum of squares and SP stands for sum of products:

$$SS[1] = \sum (X_{1i} - \bar{X}_1)^2 = \sum X_{1i}^2 - (\sum X_{1i})^2 / N$$

$$SP[1,2] = \sum (X_{1i} - \bar{X}_1)(X_{2i} - \bar{X}_2) = \sum (X_{2i} \cdot X_{1i}) - (\sum X_{1i})(\sum X_{2i}) / N$$

where N is the number of points and the summations are from i = 1 to N.

The curve-fitting procedure first fits an annual harmonic (P = 365 days) to the original data set. The mean, cosine, and sine coefficients are determined by the above expressions. The significance of the regression coefficients is tested as described by Fofonoff and Bryden (1975) and Brownlee (1965). If the annual curve is significant at the 95 percent level, it is accepted and the residuals (*i.e.*, the differences between the original data and the calculated annual curve) are the input data for fitting the second harmonic with a period of 365/2 days. The significance of this curve is tested. If accepted, the residuals are again determined and a third harmonic with P = 365/3 is fit to them. The second and third harmonics will have small mean values associated with them. The mean value for the year is the sum of the three means.

The inclusion of a fourth harmonic (P = 365/4) does not provide any statistically significant improvement in the results, and, therefore, only the first three harmonics are considered.

The standard deviation of the original temperature data from the combined annual curve is determined. Any points that are more than two standard deviations from the calculated curve are identified. The curve-fitting process is repeated with these points omitted to prevent the rare occurrence of an external water mass (*e.g.*, slope water or Gulf Stream water) from distorting the calculated annual cycle of the dominant, local water mass. The results of the second curve fitting are the values accepted and used.

An example of the curve-fitting results is shown in Figure 2 for the bottom temperature at MARMAP station 56, located in the inner New York Bight. The solid line is the mean annual curve and the dashed lines represent plus and minus one standard deviation from the mean. The original data points are plotted and keyed by year. The calculated mean curve follows the observations quite closely. The standard deviation results more from real interannual variability in the data than from an inability of the curve-fitting method to represent the original data.

A program for personal computers that uses these calculated annual curves to estimate the temperature anywhere on the shelf on any day of the year is presented by Mountain (1989).

Temperature Distributions

Using the annual curves for the MARMAP stations, the shelfwide distribution of temperature can be determined

Figure 2. Calculated annual curve (solid line) for the bottom temperature at MARMAP station 56. The dashed curves represent plus and minus one standard deviation from the mean curve. The original data points are plotted with symbols indicating the year of the observation.

easily for any day of the year. The value for each station is calculated from its annual curve and then the values for all stations are plotted and contoured. The distributions for the expected surface and bottom temperature for the beginning and middle of each month are presented in Figures 3 through 26. The standard deviations of the surface and bottom annual temperature curves are presented in Figure 27 and are an indication of the interannual variability in temperature conditions. In most areas, this variability is between 0.5 and 1.5°C.

The analytical form of the calculated annual curves allows other characteristics of the seasonal cycle of temperature on the shelf to be determined. The annual range of expected temperature is shown in Figure 28. The progression of the warming cycle along the shelf, indicated by the day of the year (Julian day) that the surface temperature first reaches 7°C in the spring, is shown in Figure 29. An indication of the timing of seasonal cooling is shown by the first day the surface temperature falls below 12°C (Figure 30). The spring warming progresses along the shelf from south to north. The fall and winter cooling, however, progresses primarily from the coast seaward across the shelf.

The data used to derive the temperature distributions presented were obtained over an 11-year period, 1977-87. In using these distributions, it is important to appreciate how the temperatures during these years compared to long-term climatic conditions. Figure 31 shows the annual average surface temperature at Boothbay Harbor, Maine, since 1906 (Churchill 1988). The average temperature for 1977-87 was 8.55°C, which is close to the average for the whole record of 8.33°C. The recent decade was intermediate between the high temperatures of the early 1950s and the cold conditions in the early 1940s and mid-1960s.

Acknowledgements

Numerous people worked many years to collect and process the temperature data used in this report and to them as a group the authors wish to express their gratitude. The 11-year time series of data would not have existed without the perseverance of Dr. Kenneth Sherman. James Manning wrote the computer programs that produced the contour figures in this report.
